## Abstract

### Purpose

As obesity rates continue to climb, the notion that overconsumption reflects an underlying ‘food addiction’ (FA) has become increasingly influential. An increasingly popular theory is that sugar acts as an addictive agent, eliciting neurobiological changes similar to those seen in drug addiction. In this paper, we review the evidence in support of sugar addiction.

### Methods

We reviewed the literature on food and sugar addiction and considered the evidence suggesting the addictiveness of highly processed foods, particularly those with high sugar content. We then examined the addictive potential of sugar by contrasting evidence from the animal and human neuroscience literature on drug and sugar addiction.

### Results

To what extent has your ability to conduct research been impacted by COVID-19 since the beginning of the year, and what is your expectation on how it will continue to be impacted over the coming months?

We find little evidence to support sugar addiction in human addiction-like behaviours, such as bingeing, occur only in behaviours likely arise from intermittent access to sweet tastes and effects of sugar.

## Conclusion

Given the lack of evidence supporting it, we argue against scientific literature and public policy recommendations.

## Introduction

Between 1980 and 2013, the proportion of overweight (body mass index (BMI)  $\geq 30 \text{ kg/m}^2$ ) adults rose from 28.8 to 36.9 % worldwide adolescents [1]. The accompanying costs of health consequences are estimated to range from \$3.38 to 6.38 billion annually in the United States [2]. The scale and impact of the obesity pandemic demands extreme care and careful scrutiny of existing evidence and concepts. In this spirit, we wish to evaluate sugar addiction consequences in terms of public policy and health advice if

The food addiction (FA) model asserts that excessive consumption of the same neurobiological framework as drug addiction. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) [3] defines FA in the neuroscientific literature. It is characterised by loss of control over consumption, and a persistence of drug taking despite negative consequences. FA research has been extensively studied (see [3, 4]). Individual symptoms analogous to those of drug abuse, including loss of control over consumption of various foods, such as corn, milk, eggs, and other foods, have changed since this original description (see [7]), and there is evidence that sugar and fat, are most likely to be addictive. FA research will open new avenues for prevention, treatment, and other aspects of the model, has been questioned [10, 11].

Sugar addiction represents a specific case of the FA model in which the addictive substance is the specific nutrient sugar. In this perspective article, we consider the state of the evidence in support of sugar addiction in humans and provide a critical review of the preclinical neuroscience research that has identified sugar addiction in rodent models. This is important because few studies have specifically examined sugar addiction in humans, and the bulk of supporting evidence comes from animal work. However, there is a methodological challenge in translating this work because humans rarely consume sugar in isolation. In order to assess the existing evidence, we must first consider whether sugar could be an addictive agent, examining specifically the animal neuroscientific evidence suggested to support this. As the animal neuroscience of sugar addiction draws strong parallels to drug addiction, we review the sugar and drug addiction neuroscience side by side. We go on to consider the human model of FA to determine whether and how it could be applied to sugar.

## Characterising (potentially) addictive foods

A general view is that FA is similar to substance addictions, rather than non-substance behavioural addictions outlined in the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5, for a different perspective, see [12]), in that certain ‘addictive agents’ within food produce neurochemical effects in the brain similar to drugs of abuse. The Yale Food Addiction Scale (YFAS [13] and recently the YFAS 2.0 [14]), which is

now the widely accepted measurement tool for studying FA with respect to 'certain foods'. These scales do not specify usually consume food with multiple nutrients. Even foods that contain a single nutrient (e.g. sugar-sweetened beverages) have flavour(s) and the addictive potential of different foods may provide an insight that is critical in determining addictive potential.

Evidence from rodent models supports high-fat [15], high-sugar [17] and high-fat and high-sugar [17] foods as candidates for FA. In humans, it is clear that highly processed, hyperpalatable foods are the ones that are most likely to be addictive. The question surrounding what might constitute an addictive food poses a challenge. Two studies have examined the addictive potential of various

Schulte et al. [5] suggest that certain highly processed food items (the term can be used for food), such as high potency and rapid absorption (e.g. high sugar and high fat) report that such processed foods are strongly associated with YFAS. Their findings also demonstrate that fat content and sugar content (per serving) predict ratings of problematic foods, where processed foods are more problematic. In this study, highly processed foods were found to be high in carbohydrates (high GL) that may also contain low levels of protein. The authors argue that processing of raw foods increases the foods' 'potency' (e.g. fat, sugar, salt) into the bloodstream, as indexed by increased consumption.

Fowler et al. [19] hypothesised that individuals who develop FA would be more likely to have had problems with foods that are high in fat and sugar. For this, they used foods listed in the YFAS and categorised them based on fat and sugar content. Findings indicated increased likelihood of FA in individuals who endorsed high-GI and high-sugar, low-fat (but not high-sugar) foods. The authors concluded that these patients might have experienced undiagnosed FA. These findings should be interpreted in the context of the retrospective recall of 'problem foods', only two foods (candy and fat). Furthermore, analyses of the relationship between problem foods and current or previous psychiatric morbidity, success of subsequent treatment suggest caution in arguing that such foods are addictive based on the YFAS [20].

To describe the difference between foods such as cupcakes and bananas primarily as being one of the degrees of processing is perhaps a rather narrow view, and a strong case can be made for these foods having other important differences relevant to overconsumption and obesity (e.g. energy density). Even leaving this aside, there are several important concerns about both of these studies. First, the potentially addictive foods have been taken from the 'problem foods' list of the YFAS. The scale quantifies FA symptoms with respect to these problem foods, based on the assumption that they are likely to be addictive. Both of the aforementioned studies rely on this assumption and take the evidence that individuals have reported FA symptoms with respect to these foods on the YFAS in several studies, as further supporting the assumption. Second, these findings rely entirely upon participants' perceptions of difficulties surrounding the food items, which are then linked (by way of a mechanistic explanation not empirical evidence) via GL or GI to postprandial glucose and insulin. That is, no direct evidence indicates that these foods are problematic for these individuals because they lead to higher postprandial glucose. Although individual postprandial glucose response (PPGR) has low intra-personal variability, there can be high interpersonal variability in PPGR following the consumption of identical meals [21, 22]. For example, Zeevi et al. [21] found that PPGRs for cookies and bananas varied significantly across participants, suggesting that some individuals may be high glucose responders to 'good' foods and low responders to 'bad' foods. It is also important to note that there are several high-GI foods such as breakfast cereals and baked potatoes that are not included in the list of YFAS problem foods. This suggests that the

### Is sugar a potentially addictive substance?

The FA literature considers sugar (and other refined carboh high addictive potential, contributing to their GL (dose) and discussion of sugar has centred on its palatability or hedoni has both hedonic and caloric value, and these two aspects b of its consumption, respectively. Moreover, these aspects a processing as demonstrated in two elegant sets of experime concentrating hormone (MCH)-expressing neurons located within the lateral hypothalamus respon to extracellular glucose levels and project to dopaminergic (DA) neurons in the striatum and midbrain regions. The animals show a preference for sucrose over the non-nutritive sweetener, sucralose, and the glucose-sensing ability of these neurons is critical in determining this, as transgenic mice lacking MCH neurons do not show this preference [28]. MCH neurons encode the rewarding nutrient properties of sucrose by increasing striatal DA release independently of gustatory input. Optogenetic stimulation of MCH neurons during consumption of sucralose leads to striatal DA efflux and preference for sucralose over sucrose [28].

Recently, Tellez et al. [29] expanded upon this work by examining DA transmission in the striatum in response to oral sucralose intake versus intra-gastric glucose or sucralose administration. Using microdialysis, the authors reported changes in DA release in the ventral and dorsal striatum, where regional DA release selectively encoded the pleasurable and nutritional value of the sweet foods. Sucralose consumption was linked to enhanced DA efflux in the ventral striatum (VS), which was no longer observed following devaluation of the sweetener with a bitter additive. Conversely, intra-gastric infusion of glucose, but not sucralose, elicited DA release in the dorsal striatum (DS). Thus, the VS and DS appear to encapsulate functionally distinct responses to palatable and nutritive signalling, and the authors went on to delineate the role of D1 and D2 striatal DA neurons in palatability and nutrient preferences. Dopaminergic signalling excites D1 DA neurons while inhibiting their D2 DA counterparts, and this interaction modulates the control of goal-directed actions, including overeating [17]. Optogenetic stimulation of D1 DA neurons within the DS and substantia nigra terminals increases consumption of a bitter sucrose solution, which supports the dorsal basal ganglia pathway as a circuit that is selectively

responsive to the nutrient properties of sugar reward [29]. In D1 DA, and D2 DA neurons has yet to be explored in animals. The aforementioned neural circuits reflect processes underlying

This experimental work allows us to consider that addictive mechanisms: one related to palatability and the reinforcing and post-ingestive effects, and a third arising from a combination. The 'addictive' quality of sugar may be restricted to its sweetness. Of course, only the third possibility would support sugar as where highly processed foods with added sugar would be vulnerable. Therefore potentially have a characteristic profile of ingestive. Often consume sugar in combination with other nutrients, and low addictive potential would need to be characterised. Foods can have very different post-ingestive profiles in different aspects of individual vulnerability to a potentially addictive. Little work in humans has examined them directly. The animal evidence of parallels between sugar and drugs. We consider an overview of the neurobiological characteristics of drug addiction.

## Animal models of drug addiction

Prevailing models of drug addiction emphasise changes in mechanisms involved in the transition from voluntary drug releases DA within the mesolimbic system which reinforce of, and subsequent motivation towards, drug-related cues [30]. The nucleus accumbens (NAcc) shell, yet this response becomes blunted [31]. Instead, drug-related cues produce an anticipatory DA [32]. This has been framed as an increased anticipatory reward. Activation in the dorsal striatum and basolateral amygdala becomes increasingly elicited by drug-related cues, it is ultimately habit [33]. This transition from goal-directed to habitual drug rodent models of addiction to cocaine, heroin, and alcohol in humans. These compulsive behaviours arise from functional (salience, compulsivity), as well as the dorsolateral and infero-

The onset of drug addiction has been associated with decreased availability of DA D2 receptors in both humans and non-human primates [36, 37]. These findings relate low DA receptor availability to increased trait vulnerability to drug abuse; however, it has been argued that chronic drug use reduces the number of DA D2 receptors, thus resulting in a 'hypodopaminergic' system [38]. While it is likely that aberrant DA D2 receptor numbers reflect both cause (trait vulnerability to) and consequence of prolonged drug use, reduced DA D2 receptor availability has been closely tied to withdrawal symptoms and the development of drug tolerance, in which drug consumption no longer elicits a positive effect but rather mitigates a negative state [39, 40]. Together with afferent input from the amygdala, these neuronal changes in the striatum (i.e. reduced DA D2 receptors) perpetuate drug use to avoid dysphoria and withdrawal, comprising what Koob and Le Moal [41] have termed the 'dark side' of addiction.

Accordingly, in sugar addiction, one could expect to see a similar behavioural and neurobiological syndrome. Voluntary consumption of sugar under goal-directed control would increase DA release in the mesolimbic system, enhancing the salience of and motivation for sugar. Over time, sugar seeking and consumption would become habitual and compulsive with an accompanying shift from ventral to dorsal striatal control, as well as changes in prefrontal cortical control of these behaviours. These neural adaptations would serve to perpetuate sugar seeking that may also be driven by the need to avoid withdrawal symptoms. In line with research of chronic drug use, DA D2 receptor levels may represent a vulnerability marker and also result as a consequence of excessive sugar intake over time, regardless of BMI status or obesity.

# Comparison of drug addiction and su

Critical to these studies are the experimental designs used to believe that a working knowledge of these paradigms and the literature on animal models of drug and sugar addiction. The paradigms, and we will compare different aspects of drug addiction have been drawn between sugar and a variety of illicit drugs have chosen to focus on the neurobiological effects of cocaine system, and heroin, an opiate that acts upon both dopamine point out at the outset that sugar addiction literature is not a therefore, not all aspects of addiction have been examined

## General overview of experimental models

### Drugs

Rodent models of addiction traditionally frame the drug of associated with a pleasurable outcome. A drug is thought to response to the agent exceeds the response to a control, e.g. administer the drug for a short daily session of 1 to 3 h [42] trained to self-administer intravenous (IV) cocaine via a lever where each lever press prompts drug delivery (a fixed ratio or intravenously, though it is often preferred to use the route into consideration taste effects. Thus, implanted catheters are but some studies allow access to an oral cocaine–sucrose self-protocols train rodents to self-administer drugs of abuse prior vulnerability to drug addiction. As such, the use of drug-na

To model the transition to compulsive ‘drug seeking’, the rodents which they must systematically work harder (i.e. increase the Motivation is further measured by ‘breakpoints’, or the ratio of the reward, and it can be augmented by periods of drug abstinence will work for the drug despite negative consequences—a key stimuli (e.g. lever press) or outcomes are paired with aversive outcomes, such as an electric footshock or nauseating chemical additive. Following extensive drug self-administration, rodents display withdrawal symptoms in response to forced abstinence, as well as dopamine (e.g. sulpiride) and opioid (e.g. naloxone) antagonists. However, drug seeking can be extinguished throughout periods of forced deprivation by replacing the cocaine or heroin infusion with saline (for a complete review, see [46]).

In human addiction, habitual drug-seeking and drug-taking behaviour, even following sustained abstinence, is often elicited by environmental cues, acute stress, or drug exposure. Second-order reinforcement schedules represent one method by which cue-elicited reinstatement of drug seeking can be studied in animals [47]. The drug infusion is paired with an additional conditioned stimulus (e.g. illuminated light, tone) following which exposure to the conditioned stimulus has been shown to reinstate cocaine-seeking behaviour [48] and morphine administration [49] following abstinence. More recently, the conditioned place preference (CPP) paradigm has become a widely used design, in which rodents associate distinct environments with drug and saline infusions. Following abstinence, re-exposure to these environments, along with drug priming, leads to the reinstatement of habitual cocaine and heroin-seeking behaviour [50], thus modelling the circumstances under which humans often experience drug relapse.

### Sugar

Although sugar (e.g. sucrose, saccharin, glucose) reinforces within drug addiction studies, Avena et al. [16] have demonstrated to develop addiction-like behaviours with respect to sugar. Afari et al. [51] claim to, '[...] still use the same basic technique as a feeding schedule that repeatedly induces sugar bingeing and deprives rodents of food for 12 h (or in some instances, 16 h) and subsequent 12 h, during which the rats may consume either a 25 % glucose solution or a 10 % sucrose solution; the latter the 12-h period of food availability begins 4 h into the dark phase, increasing the likelihood of consuming a novel food [51]. An important feature of these experiments is that unlike the drug models, which increases usually had previous access to sucrose and are selected for the possibility of these animals having a vulnerability to develop bingeing, this schedule for 3 to 4 weeks begin to develop signs of addiction (see additional review). It is important to emphasise these addiction models with intermittent access regimes and not with ad libitum access.

## Bingeing

### Drugs

Following initial self-administration training, increased accumbens shell accumbens associated with enhanced, binge-like consumption [55–57] after saline infusion develop a binge-like pattern of consumption that is highly variable after 24 h, where increased time between binges [58]. Interestingly, binge-like self-administration of heroin in rodents self-administer the most heroin at the start of the session and reach a stable level throughout the session [57]. The reinforcing effects of low and moderate doses have been shown to elicit reinforcing effects.

Acute IV administration of cocaine preferentially increases accumbens shell to the NAcc core [60], and this is associated with the acute release of DA in both the ventral tegmental area (VTA) and the nucleus accumbens of mu-opioid receptors (MOR), which triggers a neurochemical release [61, 62]. Mesolimbic DA release elicits hyperactivity and euphoric effects following cocaine and heroin infusion, respectively. These effects can be inhibited (as evidenced by reduced self-administration) by lesions to the ventral pallidum, as well as D1 receptor blockade in the central nucleus of the amygdala, in cocaine-conditioned animals [63, 64]. As heroin has high affinity for MOR and delta opioid receptors (DOR), administration of selective MOR and DA agonists has been shown to result in heroin reinforcement that is extinguished following chemical lesioning of DA neurons or microinjections of opioid receptor antagonists within the VTA [65].

### Sugar

Binge-like sugar consumption has been observed in rodents under both 24-h and intermittent reinforcement schedules, where animals self-administer sugar on an FR1 protocol. Colantuoni et al. [66] reported that food-deprived rats increased sugar intake within the first hour of access to food, and similar bingeing patterns occur when rats receive 12-h access to both sugar and chow [51]. With the same intermittent reinforcement schedule, sham-fed rodents consume more sucrose than real-feeding controls [67], although differences are non-significant with repeated consumption. Interestingly, rodents with ad libitum access to sugar solution consume the food throughout the light phase (or inactive cycle), and total sugar intake does not differ between rodents with 12- versus 24-h access [16]. Moreover, rats fed daily intermittent sugar and chow offset sugar consumption by decreasing chow consumption, thus regulating caloric intake and preventing weight gain [68, 69]. Because

rodents with ad libitum sugar access offset caloric intake and body weight gain. [16] concluded that such experimental conditions cannot be used to study the role of intermittent access is critical to the development of bingeing to develop addictive behaviours. With respect to obesity, it is clear that both intermittent and ad libitum access schedules offset chow intake to comparable levels of stability.

These behavioural data highlight noteworthy differences between bingeing and non-bingeing. An apparent distinction arises from temporal discrepancies related to bingeing. Despite limited evidence of food restriction increasing bingeing, bingeing increases *both* cocaine and heroin intake under normal feeding conditions. Rats gain 85 % body weight (e.g. [71]). Under such conditions, it is clear that bingeing is not simply a function of abuse versus non-drug rewards; however, these processes are distinct. Following food restriction, bingeing is observed. As similar findings are seen in studies of bingeing from the reinforcing effects of a preferred flavour, rather than from the reinforcing effects of ad libitum conditions, rats dramatically increase cocaine intake. In studies where rats continue to binge throughout the 72-h period [58]. Mirrored bingeing patterns that converge with an inherent circadian rhythm are observed when rats administer cocaine during the light phase [72]. Yet, bingeing is not simply a consummatory pattern with binges occurring early in the feeding period, but rather a function of homeostatic regulation of feeding behaviour and the presence of a preferred flavour.

The neurobiology of sucrose reinforcement has largely focused on the role of dopamine in the core. Intermittent sucrose consumption persistently increases dopamine release in the core in both sham [67] and normal feeding [16] conditions. In control or ad libitum sugar access animals, and as with most other natural rewards [73, 74]. Thus, a drug-like DA response to sugar is only observed under intermittent access, suggesting a critical role of the paradigm. Corwin has raised the question of eating under uncertainty because food availability is unpredictable.

Infusion of a selective mu-opioid agonist into the NAcc has been shown to increase chocolate preference (chocolate) with identical nutrient profiles, suggesting that it is the presence of a preferred flavour rather than sucrose preference [77]. Additionally, Mice show increased sucrose intake [78]. Infusion of naltrexone (an opioid antagonist) into the NAcc decreased consumption of the preferred flavour, yet systemically administered naltrexone did not affect consumption equally. These findings, along with those of Tellez et al., demonstrate distinct neural mechanisms for sweetness and caloric content, and support the role of rewarding effects of sweet taste in this intermittent access paradigm.

Benton [54] and Dileone et al. [79] have previously argued the post-ingestive properties of glucose appear to have little effect on initial consolidation of its rewarding properties. Moreover, neurobiological changes in the striatum have yet to be reported in the absence of the intermittent sugar bingeing (i.e. with ad libitum access to sugar) [66]. In summary, the dopaminergic changes that resemble addiction only occur with sugar consumption under the intermittent access regime, and without these conditions, the dopaminergic response to sugar resembles that to other natural rewards. Conversely, cocaine and opiate drugs cause neurobiological changes within the NAcc and VS that lead to and perpetuate addiction, including changes in D2 DA receptor levels [3] and MOR density and expression [80] following chronic cocaine and opiate administration, respectively.

## Motivation and substance seeking

### Drugs

Following initial self-administration training, rodents show increased motivation for cocaine self-administration as evidenced by high breakpoints within PR schedules. Breakpoints may be manipulated by several experimental parameters, including the unit injection dose and restricted access to cocaine. For example, rats that were allowed access to cocaine 4 times/h in a 24-h period during initial self-administration showed higher breakpoints

after 7 days of abstinence when compared to rats that were assert that a progressive increase in daily breakpoints is not speed of the injection. For example, in rodents with a history of cocaine exposure, higher doses had significantly higher breakpoints than those that received lower doses. In addition, speed of initial cocaine infusion significantly altered the speed of initial cocaine infusion in rodents receiving cocaine infusions over 5 s versus those receiving saline infusions.

Unlike cocaine seeking, the emergence of heroin-seeking behaviour is associated with withdrawal symptoms, which result in increased consumption of a dysphoric state). Acute opiate exposure increases pain sensitivity and sensitisation of nociceptive systems may be related to the development of drug seeking and taking. Both forced deprivation and opiate seeking are characterised by teeth chattering, paw tremors, and erratic behaviour.

Cocaine abstinence increases motivation in rodents initially following the establishment of cocaine as a positive reinforcer power. Moreover, Vanderschuren and Everitt [71] demonstrated that forced deprivation suppress cocaine seeking in rodents with a prolonged cocaine history. The authors assessed drug-seeking behaviour within a heterogeneous population of rodents. Seeking and taking cocaine are distinct acts with separate neural substrates. Rodents seeking lemon-sucrose solutions with an aversive lithium chloride solution maintained the same level of drug seeking as rodents maintained the same level of drug seeking.

Changes in the limbic, cortical, and ventral striatal circuitry underlie drug seeking [34]. Lesioning of either dopaminergic circuitry in the basal ganglia or the NAcc core alters cocaine seeking [86]. In contrast, lesioning of the NAcc shell [87], likely by way of diminished executive control, as this region projects reciprocally to the basolateral amygdala [34], results in the development of enhanced motivation for morphine. Mice lacking dopamine D1 receptors in the NAcc demonstrate significantly higher breakpoints for responding on FR or PR schedules [88]; however, rodents with lesions of the NAcc and DS demonstrate significantly higher breakpoints for responding on FR or PR schedules [89]. Thus, converging neurobiological evidence identifies the role of dopamine in the maintenance of opiate seeking. Over time, these neurobiological changes result in the maintenance of opiate seeking and intake, resulting in the hallmark feature of addiction.

## Sugar

Enhanced motivation and sugar seeking are often achieved by forced deprivation, which has increased the number of lever presses for self-administration of sucrose solution [16]. However, these findings do not directly represent rodents' motivation for a sugar reward but rather the number of unsuccessful lever presses executed under an FR1 schedule (i.e. the lever presses in between sugar receipt). Receipt of sugar reward was not dependent upon the number of additional presses between reinforcement. A more recent study has incorporated differential reinforcement schedules, which systematically increase the time intervals between sucrose reinforcements to quantify impulsive responding for sucrose solutions [90]; however, the findings failed to demonstrate increased lever pressing across sucrose-reinforced sessions as compared to control (i.e. water) sessions. As such, motivation for sucrose appears to be less robust than that for either cocaine or heroin, though expectedly infusion of a selective mu-opioid agonist significantly increases break points for sugar pellets in a progressive ratio schedule [91].

Some research has quantified motivation for sucrose by direct comparison with other drug-seeking behaviours. In one study, some rodents preferred self-administration of saccharin over cocaine and paid a greater 'price' for saccharin than for cocaine by adhering to FR2, FR4, and FR8 reinforcement schedules [53]. Although this resembles early PR schedules in which rodents linearly increased lever presses for subsequent infusions, standard PR schedules for drug reinforcement now require rats to increase lever presses exponentially from one

infusion to the next [55]. Thus, direct comparison of these heroin reinforcement overestimates the degree to which saccharin selectivity increased cocaine consumption following the effect(s) of sweet preference on vulnerability to drug addiction. Preference for Oreo cookies has predicted greater break points in rodents that preferred rice cakes demonstrated equivalent saccharin-cocaine-seeking behaviour [93].

## Habitual use and withdrawal

### Drugs

Rodents with extended cocaine self-administration training followed by cocaine was administered, even following periods of abstinence to a stimulus (i.e. a light previously paired with lever pressing) following injections following abstinence, and the CPP paradigm rest of behaviour, thus modelling the circumstances under which habitual use occurs.

Whereas the acute reinforcing effects of cocaine are associated with the NAcc shell, cocaine seeking has been related to enhanced I of DA receptors in the anterior dorsolateral striatum, but not the dorsomedial subregion. Jedynak et al. [98] further demonstrated that prolonged stimulation by increasing dendritic spine density in the dorsolateral subregion. The authors assert that such restructuring is necessary for the emergence of S-R habits following chronic stimulant use. As discussed above, in the case of heroin, the effect of drug use as negatively reinforced by the dysphoria of withdrawal.

### Sugar

Although compulsive sugar-seeking behaviour following extended access to converging evidence suggests that animals develop CPP in response to sugar, food-deprived rodents prefer the environments in which they were exposed to [100, 101], and similar findings were reported with high-sucrose food rewards [102]. Administration of naltrexone dose-dependently disrupts CPP for sucrose, yet the opioid antagonist does not affect the development of CPP [103]. The competitive opioid antagonist naloxone precipitates withdrawal symptoms in sugar-bingeing rats, which resemble those of opiate withdrawal (e.g. anxiety, teeth chattering, forepaw tremor, head shakes) and share a similar neural profile with decreased DA and increased acetylcholine in NAcc [66]. Furthermore, Avena et al. [104] report increased anxiety in fasted rodents (36 h) that were previously maintained on an extended intermittent reinforcement schedule with 10 % sucrose solution. A similar withdrawal syndrome has been observed following 8 days of an intermittent access to saccharin [51]. It has also been demonstrated that rats on the intermittent access schedule show reduced D2 DA receptor binding in the DS [66].

## A shared neurobiology?

An oft-repeated observation asserts that food and drug consumption share a common neurobiology [105]. This is true in so far as drugs are understood to 'hijack' a neural system that primarily processes natural rewards like foods; however, important differences remain. First is the matter of the anatomical localisation of the neural circuits involved in these consummatory behaviours. Carelli et al. [106] have demonstrated that different populations of neurons in the NAcc respond to cocaine and natural rewards. Second, the dopaminergic response to sugar (and other foods) rapidly habituates, and it is attenuated by predictive cues such as smells; however, the DA response to cocaine does not habituate and is enhanced by predictive cues [31]. Third, when cue pairing to

the delivery of either sugar or cocaine is established, the case of sucrose, the DA level rapidly returns to baseline and consumption of sucrose [107] whereas in cocaine, the surge lever pressing and cocaine delivery [108]. Fourth, Pavlovian core, whereas those conditioned to drugs of abuse release I

## Summary of the animal neuroscience

Clearly, addiction-like behaviours can be elicited by sucrose. First, as evidenced by the studies using sucrose in sham-fed saccharin, it seems that these behaviours occur in response to sucrose content. Both of these findings raise another important question: sucrose that are important to the development of this addiction. Effects of drugs are critical to the development of the neurobehaviours are only engendered in a specific intermittent access development, as these behaviours are not seen in animals given a continuous regime, test animals have been pre-selected for sucrose preference. In animal models of drug addiction where drug-naïve animals are used, the prevalence of addictive-like sucrose consumption remains low. In drug addiction, where it has been estimated that between 5 and 20% of animals develop drug addiction [110–112]. Clearly, the combination of sweet and drug strongly resembles addiction in several aspects, including a dopamine component [68, 113] that seems to be mediated by mu-opioid receptor

However, even in the intermittent access model, there remains a risk of addiction. To date, increased motivation for sucrose has been implemented progressive ratio schedules to measure the role of dopamine. Extended access to sugar remain susceptible to devaluation by a novel agent, whereas cocaine- or heroin-addicted animals continue to respond. The extent of habitual responding to sugar remains understudied. Sucrose seeking has yet to be characterised. In contrast, the drug-seeking behaviours in animals with historic cocaine or heroin seeking in response to environmental cues represents a hallmark of addiction. Consumption of sugar diverges from drug addiction on several points, suggesting a need for great caution in drawing parallels between sugar and drug addiction.

## Sugar addiction in humans

There has been little empirical work examining sugar addiction in humans. Given this, we consider how sugar addiction, as a specific form of FA, might be conceptualised in humans, and we summarise experimental challenges in evaluating it, beginning with a brief overview of FA.

### The behavioural phenotype of food addiction: the YFAS and YFAS 2.0

The current FA phenotype was first operationalised in the 25-item Yale Food Addiction Scale (YFAS; [13]). Both the FA model and the YFAS conceptualised FA in terms of a translation of DSM-IV substance dependence [114] to food. Criteria include persistent eating despite negative consequences, persistent desire for food, unsuccessful attempts to cut down and impairment of functioning because of overeating. The criteria are defined with respect to ‘certain foods’, and the YFAS provides 21 examples from 5 food categories: sweets (e.g. ice cream), starches (French fries), salty snacks (pretzels), fatty foods (pizzas), and sugary drinks. The YFAS can provide a ‘diagnosis’ of FA if at least three criteria are endorsed along with clinical impairment, or a ‘symptom count’ to indicate severity of symptomatology (scores range from 0 to 7). It has become a popular and widely

used self-report measure of this construct to the extent that validity and utility have been questioned [10, 11].

The YFAS has recently been updated [14] based on DSM-5 in the YFAS 2.0. The key difference is that, in updating criteria for binge eating and dependence, the threshold for diagnosing FA has been lowered to clinically significant impairment may be diagnosed with moderate (4 or more symptoms) FA. Preliminary validation of the YFAS 2.0 found that 11.9 % of the sample met the criteria for FA, and obese individuals endorsed more FA symptoms than the non-obese group. In the YFAS 2.0, previously expressed concern of withdrawal symptoms and tolerance and how they might relate to FA is not that their presence is critical in FA; rather, the concern is that they are not adequately defined and may therefore be unreliable. Moreover, withdrawal is frequently endorsed by participants in a recent study of the YFAS 2.0, there seems to be strong concordance between the YFAS 2.0 [14]. It is important, therefore, that they are characterized by a precise definition, it is difficult to determine conclusively the relationship between withdrawal symptoms to a particular nutrient or food. Indeed, if a withdrawal symptom would offer important clues as to the nature and mechanism of the disorder, it is important to acknowledge the difficulty posed by the lack of a precise definition.

## Does food addiction represent a distinct phenotype?

FA has several shared features and high levels of co-morbidity with other eating disorders which raises the question: could it be that YFAS is indirect evidence of a distinct syndrome? BED is characterized by recurrent episodes of binge eating with loss of control over eating, which is often done in secret and is associated with disgust. It is associated with weight gain, but a significant proportion of individuals with BED have been proposed to be the strongest candidate for a distinct phenotype that FA represents an atypical subtype of BED based on a number of shared genetic vulnerabilities to drug abuse and binge eating. Individuals with FA exhibit poor impulse control and emotion regulation, as well as high levels of FA liability [118]. Davis et al. [119] found that BED was associated with the A110 polymorphism of the mu-opioid receptor gene (*OPRM1*) and the Taq1A A1 polymorphism of the dopamine D2 receptor gene (*DRD2*), both risk factors for substance use disorder. This same group also identified a dopaminergic multilocus genetic profile that is uniquely associated with FA when controlling for binge eating behaviours [120]. These data suggest a similarity between FA and substance addictions, but require further exploration in well-powered studies with the appropriate diagnostic groups is necessary.

Long et al. [116] recently carried out the first systematic review of the YFAS literature. They examined 40 published articles to address important outstanding questions about FA, including its relationship with BMI and eating disorder pathology and whether FA represents a distinct phenotype of disordered eating. The authors found a high co-occurrence of FA with BED and bulimia nervosa. An estimated 47.2 to 56.8 % of people with BED meet criteria for a FA 'diagnosis' [116], and these prevalence rates seem excessive for a diagnostic subgroup. Binge eating frequency correlated with YFAS scores in both overweight and healthy weight groups, but the relationship with BMI was less clear-cut. Some studies report non-significant differences in BMI across YFAS-diagnosed 'food addicts' and their healthy counterparts [121], while others indicate no correlation between BMI and YFAS score [122, 123]. While the prevalence rates of FA are consistently greater in overweight and obese groups (15.2 to 56.8 %), whether FA accounts for enough unique variance in obesity to be considered an explanatory mechanism for this condition remains unclear. Furthermore, the highest prevalence rates of FA have been reported in individuals with bulimia nervosa (83.6 %) [124, 125]. This finding should be interpreted cautiously as the numbers of individuals with diagnosed bulimia nervosa in these studies is small.

Nevertheless, as these individuals often maintain a healthy dissociable from BMI, particularly amongst those who have summary, the findings of Long et al. [116] provide evidence correlates of FA and suggest poor discriminant validity of t

## Defining a sugar addiction in humans

Defining sugar addiction in humans remains challenging. FA supports sugar as an addictive substance, and the animal need for palatability to be critical elements of addictive-like eating. The 'substance' of interest. Even so, there remain important questions that relate to addictive potential and whether sugar is necessary for precise, and given a commonplace behaviour like consumption of consumption that separates normal from disordered intake criteria for individual items and a necessary overall impairment. Preliminary examination of dietary profiles associated with consumption of energy-dense, nutrient-poor foods (e.g. carbohydrate score and BMI [126]). Interestingly, dietary intake of carbohydrate FA diagnoses or scores, suggesting a limited role of sugar in whether FA represents a distinct phenotype remains unclear. This is a particular difficulty. Distinguishing individuals with BF from those with a sugar (or sweet food) addiction will be a challenge phenotype.

An alternative approach would be to consider whether aspects of similarity with addiction-like behaviours, such as cravings and reports of food cravings, particularly for palatable foods like carbohydrates, in terms of their intensity, their reported frequency, and whether they are short-lived and subside with fasting as opposed to drug cravings with abstinence [54, 127]. Rogers and Smit [127] have proposed a model in terms of ambivalent attitudes to particular foods. Thus, food is not just one that should be eaten with restraint. Attempts to restrict intake are pre-occupying, and this is experienced as a craving and hence an alternative approach asks whether there is an addictive aspect to this highly debatable.

## Conclusions

In this perspective article, we have reviewed the current state of the evidence for sugar addiction. Most of the evidence is limited to the animal neuroscience literature, and it is far from convincing. Importantly, several key elements of drug addiction have not been evaluated in sugar addiction models, such as the transition to compulsive drug-taking and dose-dependent effects on addiction liability. There remains a paucity of human evidence in this area, and we did not consider the literature encompassing the behavioural and neural effects of sweet or palatable food consumption as this would be far too indirect to the question of sugar addiction. There is the problem of the dearth of data on pure sugar consumption as we rarely consume sugar in isolation, and the ecological validity of studies examining pure sugar consumption in humans would be limited.

In terms of future directions, we suggest two areas of potential interest. The first is to examine whether sweet foods with high GI/GL might cause a food addiction in humans. We have discussed the significant methodological and conceptual limitations of the human FA model and its measurement instruments, the YFAS and the YFAS 2.0, which will need to be considered in such explorations. The second is to examine the relevance of the intermittent sugar access schedule used in animal models to the development of eating disorders (and perhaps even a form of FA) in humans.

In summary, the science of sugar addiction at present is not very popular and powerful idea, but as this special issue illustrates, it comes to misconceptions about sugar. Even the most powerful explanatory power the term 'sugar addiction' has when used in the context of major public debates such as those over the UK. Although the concept as we discuss it here is far more of whether sugar addiction is a useful (if not valid) concept in our environment? From a policy perspective, it is unlikely that its presence in numerous food items, and any analogies suggest be specious. Given the multitude of interacting factors that we argue that support of sugar addiction as a primary cause is a narrow view that fails to capture the complexity of these conditions and appropriate responses. Furthermore, while there is a strong argument that it is dangerous to draw strong conclusions about evidence. There are many strong arguments for cutting down on products accordingly, yet these arguments will all stand or fall on their own merits.
